Abstract

In search of a non-invasive alternative detection of early-stage cardiac allograft vasculopathy (CAV), in this preliminary study we tested the hypothesis that interstitial fibrosis quantified with cardiac magnetic resonance (CMR) can serve as a biomarker for the detection of CAV. Late-stage CAV was detected with routine X-ray coronary angiography (XRCA), while a coronary intima-media thickness ratio (IMTR) > 1 on optical coherence tomography (OCT) was used to detect early-stage CAV. Interstitial fibrosis was quantified in the endomyocardial biopsy (EMB) and indirectly with CMR as the T_1 relaxation time and extracellular volume (ECV). CMR was performed within 48 h of a single invasive procedure with XRCA, OCT, and EMB procurement in stable HTx recipients ($n=27$; age 54 ± 13 years, 5.4 ± 3.7 years post-transplant). XRCA-CAV and IMTR > 1 were present in 15% and 75% of study patients, respectively. The T_1 relaxation times and ECV were increased in patients with XRCA-CAV ($p=0.03$ each), while IMTR and EMB interstitial fibrosis were not significantly different (both $p > 0.05$). ECV ($\rho=0.46$, $p=0.02$) and IMTR ($\rho=0.58$; $p=0.01$) correlated with the histological quantity of interstitial fibrosis, while the T_1 relaxation time ($p=0.06$) did not. The correlation of the IMTR with the EMB interstitial fibrosis tentatively validates the hypothesis that interstitial fibrosis may serve as an early indicator of CAV. Moreover, the significant association of CMR-based ECV with the magnitude of interstitial fibrosis in the biopsy suggests ECV as a potential biomarker for interstitial fibrosis due to early-stage CAV. The measurement of ECV may therefore have a role for non-invasive detection and follow-up of early-stage CAV.

Introduction

Heart transplantation (HTx) remains the definitive treatment for eligible patients with end-stage heart failure. Survival after heart transplantation has substantially increased

during the last two decades due to the significant decrease of all-cause mortality, primarily within the first 12 months. However, the mid- and long-term survival after HTx has not substantially improved [1].

Cardiac allograft vasculopathy (CAV) is still among the leading causes of mid-term and late post-transplant mortality [1], despite significant effort to increase comprehension of the complex interplay of various contributing factors

[2]. CAV is characterized by diffuse intimal hyperplasia that affects the coronary circulation in a longitudinal and concentric arteriovascular pattern [3]. Invasive X-ray based coronary angiography (XRCA) remains the routine for CAV detection, but is primarily sensitive to luminal pathology, which is a characteristic of late-stage CAV [4]. High-resolution optical coherence tomography (OCT) enables the visualization of the inner layers of the coronary artery vessel wall and has recently been used for the detection of intimal hyperplasia, which has been shown to occur already early after HTx when luminopathologic characteristics of CAV are not present [5, 6]. The spatial resolution of OCT (10–20 μm) is tenfold higher than that of intravascular ultrasound (IVUS, 100–150 μm), and while the penetration depth is lower, it thus allows for an accurate high-resolution visualisation of the tunica intima and media [6]. However, OCT-based imaging of the coronary vascular wall is not extensively applied for technical and financial reasons as well as its need for extra contrast medium, which precludes the standard application of this technique in HTx recipients with more advanced kidney disease [7]. All the same, detection of early-stage CAV remains essential, since immunosuppression with mTOR (mammalian target of rapamycin) inhibitors has the potential to slow or even stop CAV progression if introduced before the advent of irreversible damage of the coronary artery vessel wall [8].

Histological studies suggest that CAV starts with endothelial injury [2, 9], followed by capillary rarefaction [10, 11] and impaired adaptation of the myocardial blood flow to exercise-induced myocardial oxygen demand (Fig. 1). Subsequent diffuse myocardial hypoxia has been shown to result in an increase of the magnitude of interstitial fibrosis [12, 13], which led us to hypothesize that myocardial interstitial fibrosis could be not only a biomarker for late-stage CAV, but for early-stage CAV as well. Myocardial fibrosis can be quantified by gold-standard automated colour segmentation of histological images obtained from endomyocardial biopsy

(EMB) [14], and has been shown to strongly correlate with the myocardial longitudinal (T_1) relaxation time and extracellular volume (ECV) that can be non-invasively mapped with cardiovascular magnetic resonance (CMR) [15, 16]. These two quantitative CMR measures differ in that native (i.e., pre-contrast-agent) T_1 mapping is sensitive to changes in many components of the myocardium, which for example also includes changes caused by oedema, which makes it less specific in many cases [16]. The ECV, however, exploits the extracellular nature of contrast agents and is a measure of the non-cellular space that is mostly occupied by the extracellular matrix. Since the extracellular matrix is largely composed of collagen fibres, ECV correlates with the myocardial collagen volume fraction as already shown across different entities of human cardiac pathology [17, 18]. However, it should also be noted that ECV cannot be measured in all HTx recipients because of the potentially serious secondary effects of gadolinium-based contrast agents in those with more advanced renal insufficiency.

Therefore, as a proof of the concept that the non-invasive measurement of interstitial fibrosis could serve as an alternative to invasive screening of CAV, the aim of this study was to test the hypothesis that the amount of myocardial interstitial fibrosis as quantified with CMR can serve as a biomarker for the detection of CAV.

Methods

Study population

The local ethics committee approved the study; all participants provided written informed consent (Protocol CER Vaud 2016-00635). All experiments were performed in accordance with relevant guidelines and regulations. Stable cardiac allograft transplant patients ($n=27$, mean age: 54 ± 13 years) (Table 1) at least 6 months after surgery were

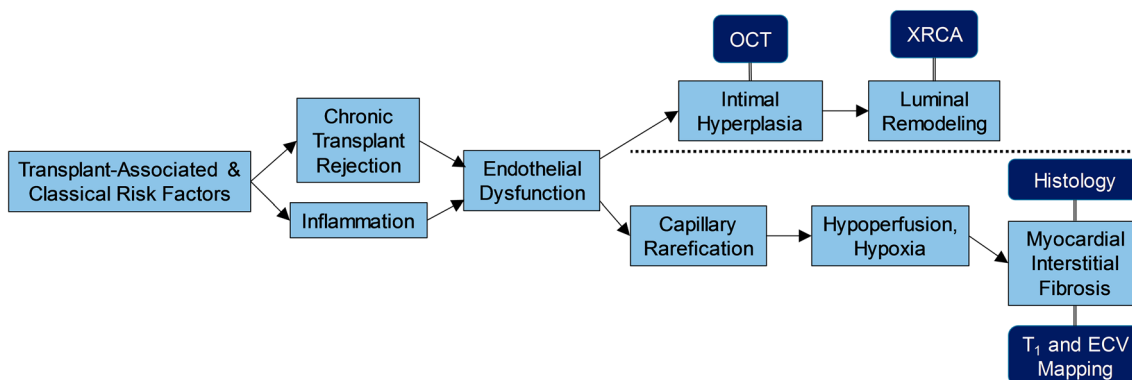

Fig. 1 Simplified pathogenesis of CAV with positioning of each of the examinations. Note that the time scale on the upper and lower part of the right side of the diagram are not the same

included (average post-transplant time: 5.4 ± 3.7 years, range 1–17 years) in order to investigate CAV from early onset to more advanced stages. HTx recipients without complete explantation of cardiovascular implantable electronic devices or with residual leads were excluded. HTx recipients with an estimated glomerular filtration rate (GFR) < 30 ml/min/1.73 m², claustrophobia, or acute cellular rejection in the preceding EMB were not included. Donor hearts were always free of segmental dyskinesia on echocardiography. Donor coronary angiograms obtained in ≥ 50 years-old donors were free of significant luminal pathology. Induction therapy in the immediate postoperative phase was started with thymoglobulin in 37% of patients and with basiliximab in 63% of study participants. Immunosuppressive maintenance therapy was adapted to the individual patient within the limits of the site-specific protocol [4]. XRCA, OCT and EMB procurement were performed within one single per-protocol intervention; CMR was always performed within 48 h of this intervention. All study participants were treated with valganciclovir for at least 3 months in the immediate phase after HTx; cytomegalovirus (CMV)-negative HTx recipients with CMV-positive donor cardiac allograft received 6 months of treatment.

Coronary X-ray angiography

Routine XRCA was performed on standard equipment (Allura, Philips, Amsterdam, The Netherlands) using a 6F guiding catheter via right radial or right femoral artery access. The coronary arteries were imaged after administration of intracoronary nitro-glycerine (50 µg) into the right coronary artery (RCA) or left main coronary artery. At least two orthogonal projections of each coronary artery were acquired. Two interventional cardiologists (J.F.I. and S.D.) independently graded the severity of CAV (hereafter called XRCA-CAV) with a scale ranging from 0 (= not significant) to 3 (= severe) on the basis of luminographic pathology [4], which remains the clinical reference standard even though it can only be used to detect late-stage CAV. In cases of differences in CAV grading, a consensus was sought after joint reinvestigation.

Optical coherence tomography

OCT was performed using a Dragonfly Optis Imaging catheter system (St. Jude Medical, St. Paul, Minnesota, USA) in 24/27 patients. The catheter was placed either into the middle segment of the RCA or the left anterior descending artery. After intracoronary administration of 50 µg nitro-glycerine, OCT imaging was performed by automated pullback over 54 mm at a speed of 20 mm/s, a radial resolution of 20 µm, and a frame density of 10 frames/mm. Quantitative cross-sectional OCT analysis was performed off-line using a dedicated OCT workstation (Illumien Optis Offline Review Workstation, St. Jude Medical, St. Paul, Minnesota, USA). All cross-sectional images were initially reviewed for quality. Frames were excluded when a side branch was present in > 45° of the cross section, in the case of inadequate image quality due to residual blood, artefact or reverberation, or if segments contained atherosclerotic plaque. The layers were analysed according to OCT consensus standard definitions [19]. The lumen, intima and media layers were traced manually every 5 ± 2 frames starting at 35 mm from the vessel ostium. Vessel layer assessment included measurements of lumen area, intima layer area and media layer area obtained by averaging the lumen-intima, intima-media and media-adventitia interface contours for the entire analysed segment. The intima-media thickness ratio (IMTR) was calculated by dividing the average area of each layer over the 35 mm of the analysed vessel. An IMTR > 1 was considered pathological [6], and will be referred to as OCT-CAV.

Histology of the endomyocardial biopsy

The quantification of interstitial fibrosis in the individual study patient was based on Van Gieson's staining [14] of

three separate EMB specimens. Slides were scanned with a NanoZoomer S60 (Hamamatsu Photonics, Hamamatsu, Japan) with a spatial resolution of 2.2 pixels/ μm (i.e., 454 nm). The percentage of fibrosis was then automatically quantified by colour segmentation with SlidePath (Leica Biosystems, Wetzlar, Germany). Samples that included scar tissues from previous biopsy sites were excluded to avoid confounding the quantification of pathological interstitial fibrosis with scar fibrosis.

Cardiovascular magnetic resonance

Myocardial segmented k-space T_1 mapping (breath-held MOLLI [20], slice thickness 8 mm, RF excitation angle 35° , echo time 1.12 ms, repetition time 3.2 ms, matrix size 256×144 interpolated to 256×218 , interpolated pixel size $1.9 \times 1.9 \text{ mm}^2$, parallel imaging (GRAPPA) factor 2, pixel bandwidth 1085 Hz/pixel) was used to assess 2 short-axis slices (1 midventricular and 1 basal) at a magnetic field strength of 3T (Magnetom Prisma, Siemens Healthcare, Erlangen, Germany) with a 32-element RF coil for signal reception. Maps were acquired before and 19–27 min after gadolinium contrast agent injection (Gadovist, 0.1 ml/kg) in the 48 h following XRCA. A 3(3)5 MOLLI scheme was used pre-contrast, while a 4(1)3(1)2 scheme was used post-contrast. Pre- and post-contrast T_1 maps were generated in Matlab (The Mathworks, Natick, Massachusetts, USA), after which the entire myocardium was segmented, and both the native T_1 and ECV of the entire segmented myocardium of both slices were computed. Cine functional imaging and late gadolinium enhancement were not performed due to time constraints. Haematocrit (Hct) was assessed as part of the routine blood workup on the same day as the EMB.

Statistical analyses

An unpaired two-tailed Student's t test was used to establish whether the presence of XRCA-CAV is linked to differences in IMTR, EMB-based quantification of interstitial fibrosis, T_1 relaxation time, or ECV. A Pearson correlation was calculated to ascertain whether there is a link between the IMTR or fibrosis on the one hand, and the T_1 or ECV values on the other hand. $p < 0.05$ was considered significant, and Bonferroni correction was used to compensate for multiple comparisons. Receiver-operator curves (ROC) were generated for all techniques to detect XRCA-CAV > 0 and IMTR > 1 , and the area under the curve (AUC) was calculated. All calculations were performed in Matlab and Prism (Graphpad, La Jolla, California, USA).

Results

No medical complications related to the procedures occurred in any of the patients. Clinical characteristics of the study participants are summarized in Table 1. Below, the measurements of vascular characteristics (XRCA and OCT) and myocardial characteristics (histology and CMR) are first reported by themselves. This is followed by the observed differences between grouped XRCA-CAV-positive and -negative patients. Finally, the correlations between the EMB fibrosis and the other modalities as well as the correlations between the IMTR and the other modalities are presented.

Vascular characteristics

XRCA was successfully completed in all patients (Table 2, Supplementary Table 1). Four study participants presented XRCA-CAV (15%) with an average grade of 1.5 ± 1.0 (Fig. 2a, b). Non-significant focal atherosclerotic lesions were visualized on XRCA in 11/27 patients (41%; 3 single-vessel, 3 two-vessels, 5 three-vessel disease).

High-quality OCT images were obtained in 20/27 patients (74%, Fig. 2c–f); insufficient image quality was caused by incomplete blood washout during data acquisition ($n = 4$ patients), diffuse atherosclerosis ($n = 2$ patients), and technical complications ($n = 1$). Most OCT data were acquired in the right coronary artery ($n = 18$ patients); 2 datasets were obtained in the left anterior descending coronary artery because of anticipated

Table 2 Summary of the main findings with the different modalities. Continuous variables are reported as mean \pm standard deviation in all patients, followed by the range

X-ray coronary angiography	
Procedure successful (% of all patients)	100 (27/27)

incomplete blood washout in the dominant RCA. Pathologic IMTR was present in 15/20 patients (75%); the average IMTR was 1.56 ± 0.63 (range 0.68–2.71). All patients with XRCA-CAV had IMTR > 1; their average IMTR was 2.01 ± 0.81 .

Myocardial characteristics

Histological analysis of the EMB was performed in 25/27 patients (93%, Fig. 3a, b, Table 2); 1 EMB was scar tissue only, and 1 procurement was not performed due to technical difficulties. Colour segmentation demonstrated a wide range of interstitial fibrosis (average $29 \pm 20\%$, range 5–78%).

CMR resulted in high-quality pre- and post-contrast T_1 maps in all patients (Fig. 3c–f). The myocardium appeared homogeneous on all native and post-contrast maps, i.e. no focal or patchy T_1 elevation was observed, which indicates the absence of magnetic field inhomogeneities, artefacts, and focal disease. The average myocardial T_1 relaxation time was 1256 ± 49 ms (range 1169–1382 ms) pre-gadolinium, while it amounted to 623 ± 61 ms (range 544–852 ms) post-gadolinium. This resulted in an average myocardial ECV of $31.9 \pm 4.8\%$ (range 26.5–49.8%).

Associations with XRCA-based detection of CAV

Interstitial fibrosis quantified by colour segmentation of the EMB as well as IMTR were not significantly different between groups with or without XRCA-CAV ($p=0.11$ and $p=0.25$, respectively), although both were numerically higher in patients with XRCA-CAV (Fig. 4a, b). By contrast, T_1 values and ECV were both significantly higher in recipients with XRCA-CAV ($p=0.03$ both, Fig. 4c, d). The ROC analysis for the detection of XRCA-CAV > 0 showed a similar moderate AUC for all techniques: 0.74 ($p=0.14$) for IMTR, 0.71 ($p=0.14$) for histology, 0.73 ($p=0.15$) for the T_1 relaxation time, and 0.75 ($p=0.12$) for the ECV.

Correlations with interstitial fibrosis and intimal thickening

The magnitude of histological interstitial fibrosis correlated by trend with the native T_1 relaxation time ($\rho=0.37$; $p=0.06$) and significantly with ECV ($\rho=0.46$; $p=0.02$, Fig. 5a, b) in accordance with previous studies reporting on other human cardiac pathologies [21, 22]. IMTR was significantly correlated with the amount of histological interstitial fibrosis ($\rho=0.58$; $p=0.01$, Fig. 6a), but was associated with

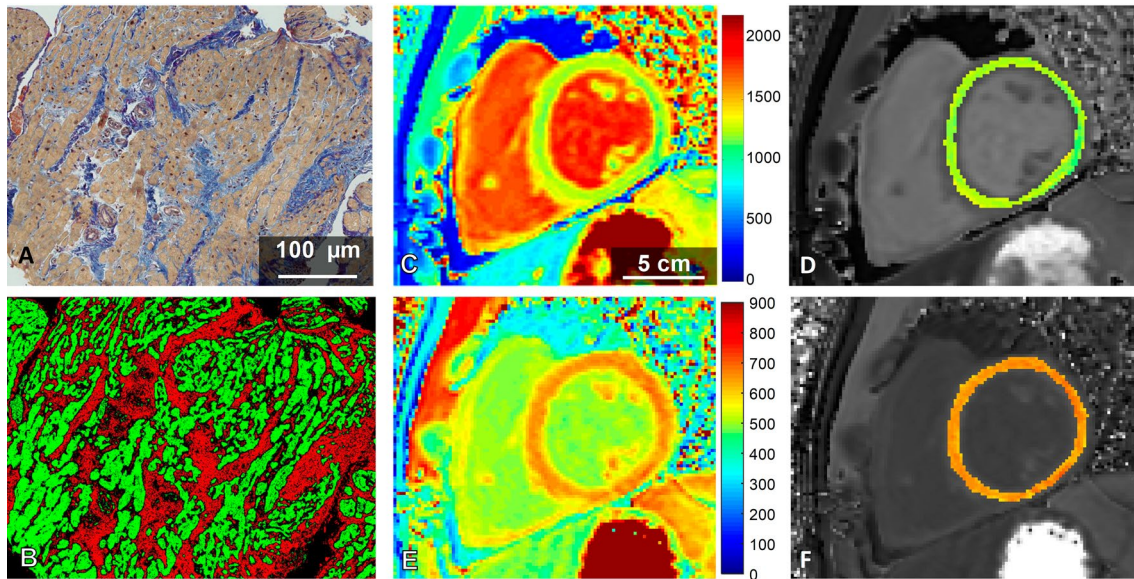

Fig. 3 Quantification of myocardial interstitial fibrosis. **a** An EMB is stained blue for collagen and brown for muscle. **b** Automated segmentation of the same slide, with a clear delineation of myocytes (green) and fibrosis (red). **c** A midventricular native T_1 map demonstrates a homogeneous myocardium with slightly elevated relaxation times ($T_1 = 1232 \pm 46$ ms). cardium in colour overlaid on the rest of the map. **e** Post-contrast T_1 map at the same location. Note the different scale. **f** Segmented myocardium of the post-contrast T_1 map. The ECV calculated from the two T_1 maps was $32.7 \pm 1.4\%$. Note that the ECV was not mapped pixel-wise, but was calculated from the averaged value of the entire segmented myocardium

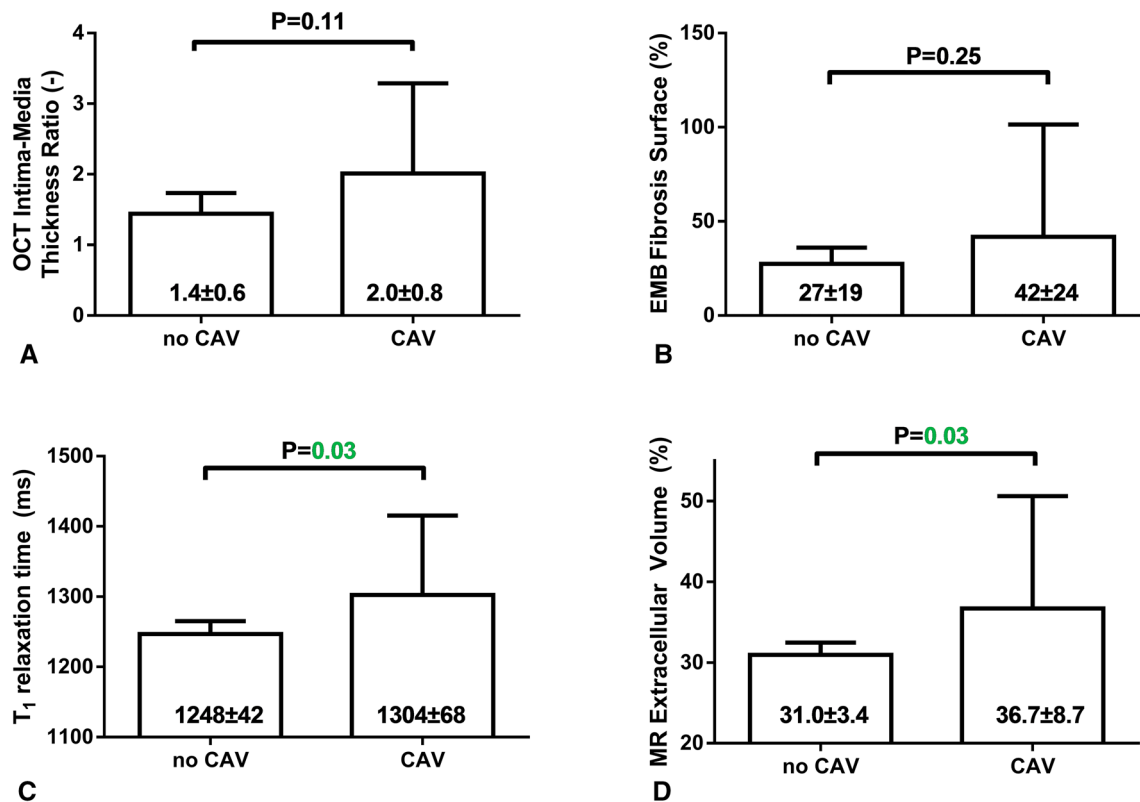

Fig. 4 Effects of cardiac allograft vasculopathy (CAV) as observed on X-ray coronary angiography. **a, b** The intima-media ratio obtained with OCT and the percentage of fibrosis in biopsies show a non-significant trend towards elevation in the presence of CAV as determined

by XRCA. **c, d** Patients with CAV demonstrated a significantly higher T_1 relaxation time and ECV than their counterparts without CAV. Numbers state the mean \pm standard deviation; error bars indicate the 95% confidence interval

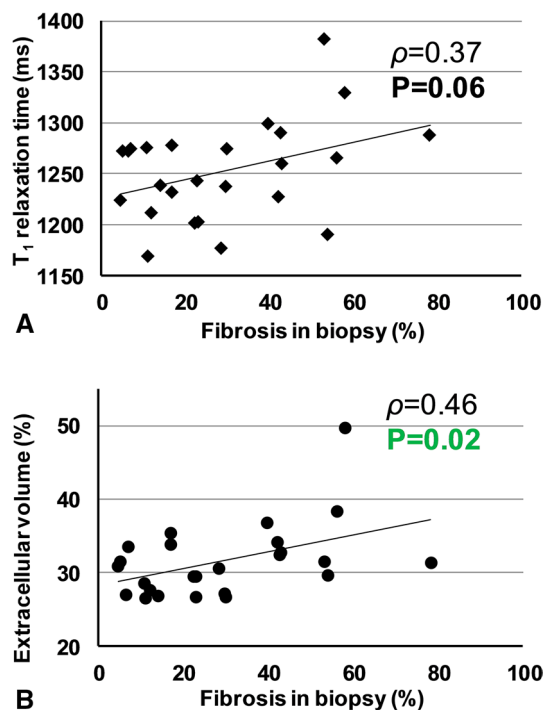

Fig. 5 Correlations of biopsy-derived interstitial fibrosis and parametric mapping. The Pearson correlation coefficient ρ and its significance p are indicated. **a, b** EMB fibrosis correlates weakly with the T₁ relaxation time and strongly with the ECV in the patient cohort

neither the T₁ relaxation time nor with the ECV (Fig. 6b, c). The ROC analysis for the detection of OCT-CAV (i.e. IMTR > 1) agreed with these observations, and resulted in low AUC values for the XRCA-CAV score (AUC = 0.67, $p=0.26$), T₁ relaxation time (AUC = 0.55, $p=0.63$), and ECV (AUC = 0.68, $p=0.27$), while the histology had a moderate AUC of 0.79 ($p=0.07$).

Discussion

In this study we used five different measurements of pathologic features associated with cardiac allograft vasculopathy (CAV) in order to assess whether interstitial fibrosis as quantified with CMR could serve as a surrogate marker for CAV. XRCA was used for characterization of late-stage CAV with luminal pathology, while OCT was applied for detection of intramural disease that is representative of early-stage CAV. The amount of interstitial fibrosis, already known as a primary non-vascular sequela of CAV in its later stages [23, 24], was quantified both histologically in the EMB and indirectly by CMR-based mapping of the T₁ relaxation time and ECV—both recently established techniques in clinical routine [16]. This study confirms (1) the hypothesis that the amount of interstitial fibrosis in the biopsy of the cardiac allograft increases with the intima-media thickness ratio

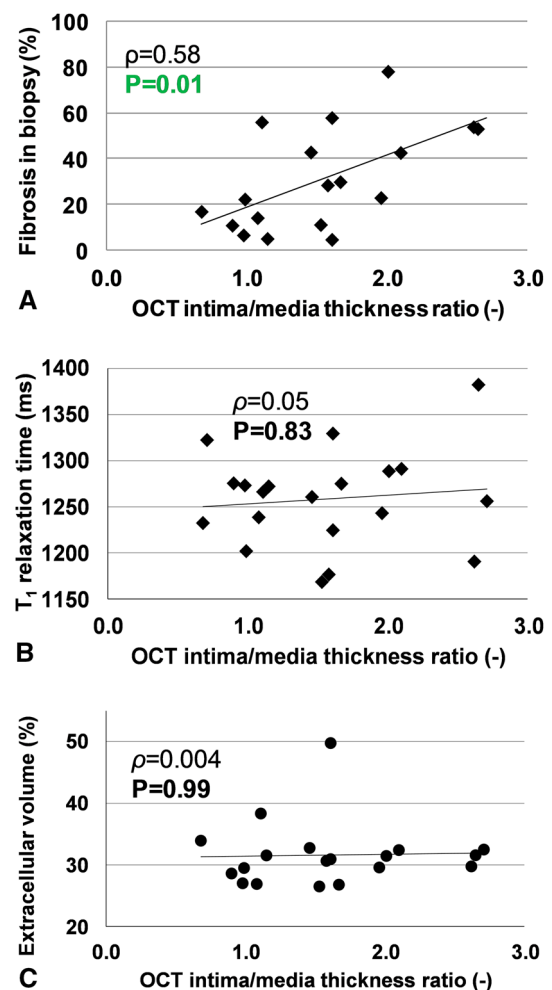

Fig. 6 Correlation between the OCT intima-media thickness ratio (IMTR) and the measurements of interstitial fibrosis. **a** Despite assessing the tentative effects of CAV at different locations in the heart, IMTR and the interstitial fibrosis in the EMB correlate significantly. **b, c** There is no correlation between the IMTR and either myocardial T₁ relaxation time or ECV

(IMTR), which is the most sensitive marker for early-stage CAV [25], and (2) that the measurement of ECV correlates with the magnitude of interstitial fibrosis in the biopsy.

CAV remains a major limitation for long-term success after cardiac transplantation. However, recent evidence suggests that conversion of immunosuppression to the mammalian target of rapamycin (mTOR) attenuates disease progression in particular in cases with early-stage CAV [23, 24]. Recently, OCT has been used to show that the intima area increases by 20% within the first year after HTx while there was an overall 2% decrease of the coronary lumen [25]. These results indicate that intimal pathology already occurs early after HTx, and that OCT is highly suited for diagnosis and follow-up of early-stage CAV. OCT measures in the present study showed that a pathological IMTR of > 1 was present in 75% of all study participants, while luminal

(late-stage) pathology associated with CAV was present in only 15% of all study participants. The high prevalence of pathologic IMTR can explain why IMTR was not significantly different between HTx recipients with or without XRCA-CAV suggesting that intimal hyperplasia preceded the advent of intraluminal pathology in the majority of study participants [4]. In fact, every study participant with XRCA-CAV had a pathologic IMTR in the present study. These observations together with the widely different prevalence of intraluminal CAV pathology and pathologic IMTR provide further support to the idea that intima proliferation precedes luminal pathology [6, 23, 25] and that OCT is the most suited diagnostic means for detection of early-stage CAV.

However, OCT is an invasive, expensive, and technically demanding exam, which limits its broad application. We therefore investigated the interrelation of interstitial fibrosis with early-stage CAV. IMTR correlated strongly with the magnitude of interstitial fibrosis in the endomyocardial biopsy in the present study, indicating that early-stage CAV is already associated with an increase of cardiac allograft interstitial fibrosis. In fact, in another study it was found that the magnitude of interstitial fibrosis increased with time after heart transplantation, and that this progression was accompanied with an augmented expression of biomarkers of hypoxia, the oxygen sensor prolyl hydroxylase 3, and the vascular endothelial growth factor [13]. The increase of myocardial fibrosis is thus most likely not exclusively limited to advanced vasculopathy as suggested earlier [26], but might occur already with early-stage CAV. This makes the detection of early-stage CAV even more essential, because the increase of myocardial fibrosis contributes to diastolic and systolic dysfunction of the cardiac allograft [27], which reduce the benefit of heart transplantation.

Native T_1 mapping and ECV measurement introduced novel quantitative metrics for the assessment of alteration of tissue composition after heart transplantation. Post-contrast T_1 mapping, which can be seen as a quantitative version of the widely used late gadolinium enhancement (LGE) imaging, did not reveal focal signal elevation in the present study. This indicates the absence of scar tissue, which can result either from more severe acute rejection or from advanced CAV with occlusion of peripheral coronary segments. ECV correlated well with the amount of interstitial fibrosis in the biopsy, which is in accordance with findings in studies of other cardiac pathologies [17, 18]. Although significant, the correlation coefficients are still relatively low, which might be attributed to the small sample size and the heterogeneous patient population. We did not observe a correlation between the IMTR and ECV, while both correlated with histological interstitial fibrosis. At this point it remains to be determined whether this observation relates to the number of study participants or the largely different spatial resolution and coverage of OCT and CMR. No local cohort of age-matched

healthy volunteers was available to put the T_1 and ECV values obtained at 3T in a local context; this remains of interest for follow-up studies.

The main limitation of this pilot study is the small number of included patients, which can explain the low to modest areas under the curve (AUC) in the ROC analyses and the associated non-significant p-values. However, it should be noted that other studies in which OCT was applied for the detection of early-stage CAV included a similar number of study participants [6, 25]. Larger patient numbers were only investigated after pilot studies [28, 29], which is most likely related to the complexity and cost of OCT-based investigation.

In conclusion, the present pilot study tentatively confirms the hypothesis that CAV as established by pathologic IMTR in OCT is already associated with increase of histological interstitial fibrosis. Similar to other human cardiac pathology, ECV measurement and histological interstitial fibrosis correlated well in this study suggesting that a CMR-based ECV measurement provides an option for non-invasive detection of the magnitude of interstitial fibrosis in the cardiac allograft. These promising results need further investigation in a larger scale study, which should test both prediction of ECV for CAV and the reproducibility of this measure for follow-up in clinical routine.
